3 Abstract

4 This is the text of the abstract.

5 Introduction

6 Biodiversity surveillance is being revolutionized by DNA-based detection of organisms from en-
7 vironmental samples. ?(specifically speed and scope of ecological studies). Many researchers are
8 justifiably cautious about the ?(adoption) of this new form of data. Their apprehension is rooted
9 in the premise that traditional survey approaches are more accurate because the chain of inference
10 between observation and ecological data is usually short: A researcher sees two swans in Lake Hopat-
11 cong and infers the lake is occupied by at least 2 swans. DNA based surveys, on the other hand,
12 consist of a longer chain of inference: DNA sequences are reported by a sequencing machine, the
13 machine identifies the sequence of products of a polymerase chain reaction (PCR), PCR amplifies

pieces of DNA from a purified genomic DNA sample, DNA is purified (extracted) from an environ-mental sample, environmental samples contain DNA from organisms present, the organisms present are representative of the biological community about which we wish to make inference. ?(reverse order? tie to concrete example (swans of Lake Hopatcong)). Clearly, this process is more complex than visual surveys, as the relationship between several steps is complex or unknown. But consider that the processes ?(behind | underlying) other more widely-used ecological survey techniques are similarly complex, such as bird surveys based on song, or visual identification of fungal spores. When alternate survey approaches are impossible or inefficient, we are more willing to accept any available survey data, regardless of the complexity or uncertainty underlying it. (microbiologists have enthusiastically relied on DNA-based surveys for years for this reason, (though yes, they also do not have the problem of disconnect between individual and cell)).

The ability of DNA surveys to make quantitative inference about communities has been touted by some (CITE new fish quantitation paper) and doubted by others (CITE european eelgrass PLOSONE). For example, a study linking (blah blah blah) concluded that "metabarcoding is pow-erful, yet blind" (CITE european eelgrass). Conversely, others have reported strong quantitative and intuitive links between DNA-based and traditional survey methods (CITE Port 2016 MOLECO). These studies usually rely on simple statistical models to link DNA quantity to some measurable ecosystem property like biomass (but see CITE). When confronted with data collected in ?(com-plex ways/studies/whatever), simple models ?(may | often) fail to detect relationships when they exist, or vice versa ?(they are prone to inflated risk of BOTH type I and type II error) (CITE, see Woltman 2012). For example, (CITE, look for that Gelman paper) have demonstrated that when data are structured in a hierarchical fashion (e.g. test scores of students in schools belonging to districts belonging to states), a low number of replicates at the first level of hierarchy (SEE THE PAPER). Similarly, (describe hospital/school problems).

Shelton et al. (CITE Shelton 2016) outlined an approach for structuring statistical models of DNA surveys that address these issues. This framework improved on alternative statistical techniques by explicitly accounting for the ?(hierarchical | nested | multilevel) structure of the study design, which allows error and uncertainty at each level to be ?(explicitly accounted for| modeled | propagated throughout the model). That study demonstrated an improvement in the estimate of higher-level (e.g. ecological community) quantities when the processes linking them to

44 the data are specified. As an example, it was shown that incorporation of data about the mismatch

45 between primer and template DNA sequence can improve the estimate of the relative abundance of

46 unique DNA templates input to a PCR.

47   Here, we apply this framework to a DNA survey of ?(nearshore | coastal) marine habitat. (TODO

48 add commentary on current dogma surrounding distribution of DNA in well-mixed (marine) habi-

49 tats). We document the variability associated with lab based ?(procedures | replication | treatment;

50 i.e. filter+DNA+PCR+seq), and the spatial scale over which DNA communities vary in this habi-

51 tat. We ?(show that | tested whether) a taxon's spatial distribution predicts (the slope of the

52 relationship between distance from shore and DNA abundance or to what degree DNA abundance

53 is explained by distance from shore for each taxon). We focus partly on species with known life

54 histories that define their spatial distribution (e.g. shallow water livebearing fishes or sessile inter-

55 tidal organisms with ?(motile/planktonic/pelagic) larvae or gametes). For these taxa whose spatial

56 distribution is well-documented and restricted, we calculate the rate of change in space and compare

57 this rate among taxa with similar spatial distributions. In turn, the distribution of rate of change

58 serves as an estimate of the spatial distribution of DNA in this habitat.

59   We would love to estimate the minimum distance over which eDNA community differences can

60 be detected.

61   Some authors have cautioned against the use of DNA-based macrobial communities in marine

62 environments because they are subject to dynamic physical forces (CITE). If environmental circu-

63 lation In general, the relationship between community dissimilarity (0 = identical; 1 = completely

64 different) and spatial distance is expected to be asymptotic, because communities nearer to each

65 other tend to be more similar than those farther apart. The intercept is expected to be near 0,

66 because samples taken at the same place should be very similar. Deviation in the intercept from

67 0 indicates heterogeneous community composition/structure over fine scales. A flat relationship

68 between dissimilarity and distance indicates that heterogeneity is not assorted spatially, and can be

69 interpreted in different ways, depending on the mean. If the mean is near 1, the spatial heterogene-

70 ity has overwhelmed the spatial scale of sampling. If the mean is near 0, there is no community

71 heterogeneity over the scale sampled.

Methods

Environmental Sampling

Starting from lower-intertidal patches of *Zostera marina*, we collected water samples at 1 meter depth from 8 points (0, 75, 125, 250, 500, 1000, 2000, and 4000 meters) along three parallel transects separated by 1000 meters (Figure 1).

Laboratory Methods

Samples were randomly assigned to PCR primer and library adapter index sequences. The sequencing run consisted of 14 samples ('libraries') prepared using different index sequences ligated during library preparation. Of these libraries, ten comprised of amplicons prepared using the 16S protocol reported above, and four comprised of amplicons prepared using a 12S protocol similar to that reported by (CITE PORT 2015).

Pooled libraries were sequenced on the Illumina NextSeq platform at the Stanford Center for Functional Genomics (machine ID: NS50061; run ID: 115; flowcell ID: H3LFLAFXX). Raw sequence data in fastq format is publicly available (see Data Availability).

Data Preparation (Bioinformatics)

Detailed bioinformatic methods are provided in the supplemental material, and scripts used from raw sequencer output onward can be found in the project directory on GitHub (see Data Availability).

We calculated rates of cross-library contamination by counting occurrences of primer sequences: 12S primer sequences appearing in a 16S library (and vice versa) indicate an error in the preparation or sequencing procedures.

We assessed PCR contamination by evaluating the dissimilarity of replicate PCRs of the same DNA sample, and removed one sample for which the Bray-Curtis dissimilarities between itself and the other replicates exceeded 0.1 (lib_B_tag_GCGCTC).

To scale the OTU counts, we calculated the minimum number of OTU-assigned reads (as opposed to raw number of reads) found in these samples (130402), multiplied this by within-sample proportional abundance of each OTU, and finally rounded these numbers.

4

Community Analysis

We subset the data in a variety of ways and conducted each analysis on all subsets. We report the subset used with each analysis, and report results on alternative subsets in the supplemental material. For all analyses beyond the assessment of PCR consistency, we use the mean taxon abundance across PCR replicates from each of the 24 environmental samples. Our subsetting methods were (1) exclude rare taxa ?(threshold)?, (2) exclude abundant taxa ?(threshold)?, (3) subsampling of taxa randomly, (4) subsampling of taxa proportional to their abundance, (5) subsampling of taxa inversely proportional to their abundance, (6) exclude taxa found in only one environmental sample (spatially invariant), (7) exclude non-marine taxa (e.g. humans, pigs), (8) exclude taxa whose known individual range (including gametes and larvae) exceeds the spatial scale of our study. We also tested a variety of transformations of the mean scaled abundance data, including (1) log ($log_e x$), and (2) binary ($1 = x > 1; 0 = x < 1$).

We simultaneously assessed the existence of distinct community types and the membership of samples to those community types using a partitioning around mediods algorithm (CITE PAM, sometimes referred to as k-medoids clustering), as implemented in the R package fpc (CITE fpc). The classification of samples to communities was made on the basis of their pairwise Bray-Curtis dissimilarity, calculated using the function vegdist in the R package vegan (CITE VEGAN).

We calculated the great circle distance between points using the Haversine method as implemented by the R package geosphere (CITE geosphere).

Spatial Model Formulation

We use the general framework outlined by Shelton et al (CITE). That study outlined the structure for estimation of the proportional biomass of a taxon (B_i) given the proportional counts of sequences recovered from a parallel sequencing run (Z_i).

We modeled the counts of DNA sequences (Z) from each of a given taxon i, in each replicate PCR j, from each replicate of a given location k (hence, Z_{ijk}), as though they are ?(proportional to/drawn from)? a Poisson distribution. A Poisson distribution is described by one and only one parameter, λ, which is equal to both the mean and variance. Because in this case our modeled

125 values are discrete counts, we use the natural exponent, e^λ. Thus,

$$Z_{ijk} \sim Poisson(e^{\lambda_{ijk}}) \tag{1}$$

126   In turn, we further assume this parameter λ is linearly proportional to a suite of taxon-, pcr-,
127 and site- specific parameters describing the variance associated with each sub-process linking the
128 amount of DNA (Y) of a given taxon i at a given location k in a DNA extract (hence Y_{ik}):

$$\lambda_{ijk} = \beta_0 + \beta_i + \eta_{ijk} + \epsilon_{ijk} \tag{2}$$

129   Where β_0 is a general intercept across all taxa, β_i is a fixed effect accounting for the variance
130 associated with taxon i, and η_{ijk} and ϵ_{ijk} are random effects of variance resulting from the processes
131 associated with PCR and spatial location, respectively.

Results

Data Quality (Bioinformatics)

134 All value ranges are reported as (mean $\pm$ standard deviation).

135 There was a very low frequency of cross-contamination from other libraries into those reported here

136 (5e-05$\pm$8e-05; max 0.00034)

137   We assessed the consistency of PCR by conducting 4 replicate PCRs for each environmental
138 sample and calculating the mean pairwise Bray-Curtis dissimilarity of the resulting communities
139 (scaled to minimum read depth per sample). 92 of the 96 amplicon samples had mean Bray-Curtis
140 dissimilarity ≤ 0.052; 1 sample had a value of 0.341, which elevates the value of the other replicates.
141 After removal of this sample, the highest mean Bray-Curtis dissimilarity among replicates within
142 an environmental sample was 0.034.

Community Analysis

144 Excluding spatially-invariant taxa ?(taxa which occur in only one spatial location) had no discernible
145 effect on the outcome of the PAM analysis (number of clusters, assignment to clusters).

146 **Spatial Model Output**

Discussion

148 Boy those results sure are neat. Now, the pressing question becomes: How do you like them apples?
